**ABSTRACT:** In mycobacteria, d-alanine is an essential precursor for peptidoglycan biosynthesis. The only confirmed enzymatic pathway to form d-alanine is through the racemization of l-alanine by alanine racemase (Alr, EC 5.1.1.1). Nevertheless, the essentiality of Alr in *Mycobacterium tuberculosis* and *Mycobacterium smegmatis* for cell survivability in the absence of d-alanine has been a point of controversy with contradictory results reported in the literature. To address this issue, we examined the effects of alr inactivation on the cellular metabolism of *M. smegmatis*. The *M. smegmatis alr* insertion mutant TAM23 exhibited essentially identical growth to wild-type mc2155 in the absence of d-alanine. NMR metabolomics revealed drastically distinct phenotypes between mc2155 and TAM23. A metabolic switch was observed for TAM23 as a function of supplemented d-alanine. In the absence of d-alanine, the metabolic response directed carbon through an unidentified transaminase to provide the essential d-alanine required for survival. The process is reversed when d-alanine is available, in which the d-alanine is directed to peptidoglycan biosynthesis. Our results provide further support for the hypothesis that Alr is not an essential function of *M. smegmatis* and that specific Alr inhibitors will have no bactericidal action.

**KEYWORDS:** NMR metabolomics, *Mycobacterium smegmatis*, *Mycobacterium tuberculosis*, alanine racemase, d-alanine biosynthesis

**INTRODUCTION**

Tuberculosis (TB) is a major global health problem, and it remains the first worldwide cause of death from an infectious disease.1 Critical challenges to achieving the worldwide goals of disease control and elimination include the appearance of multiple and extensively drug-resistant *Mycobacterium tuberculosis* strains, synergism with HIV driving coinfections in AIDS patients, and bacillary persistence in latently infected individuals.2 The cell wall of *M. tuberculosis* plays an important role in pathogenesis, and its biosynthesis is a major source of targets for the design of antimicrobial agents and attenuated mutants.3-5 As in other eubacteria, peptidoglycan is a critical component of the cell-wall backbone. D-Alanine is an essential building block of peptidoglycan and is required for the formation of peptidoglycan cross-links necessary to preserve cell integrity.3,5,8

The main source of d-alanine in eubacteria is its conversion from l-alanine by alanine racemase (Alr), an enzyme encoded by the alr gene.5,8 The critical role of d-alanine in cell-wall peptidoglycan biosynthesis has identified the biosynthesis of d-alanine as an important target for the generation of new antituberculosis drugs. Also, attenuated mutants devoid of d-alanine biosynthesis are a potential source for vaccine candidates. Thus alr essentiality and its role in mycobacterial physiology is core to the therapeutic value of targeting d-alanine biosynthesis. Studies on alr in the fast growing species *Mycobacterium smegmatis*, a useful model system for *M. tuberculosis*, rendered apparently contradictory results. In our initial reports, we found that the *M. smegmatis alr* insertion mutant grew without d-alanine.10-13 These data supported the existence of an alternative pathway of d-alanine biosynthesis in mycobacteria. However, contradictory results were reported as *M. smegmatis* and *M. tuberculosis alr* deletion mutants were unable to grow without d-alanine supplementation.14,15 These results negate the existence of an alternative endogenous pathway of d-alanine biosynthesis in both *M. smegmatis* and *M. tuberculosis*. In effect, d-alanine provided by Alr, or an external source, was reported to be an absolute requirement for the growth of *M. smegmatis* and *M. tuberculosis*. A rational for the
observed difference in the essentiality of *M. smegmatis* alr was attributed to the deletion mutant being a superior construct to the insertion mutant. This explanation was based on an inferred residual Alr activity despite evidence of the contrary.\(^\text{10-13}\) Furthermore, the argument ignores the fact that the insertion mutant was generated by the insertion of a drug marker that split alr approximately in the middle of the gene,\(^\text{11}\) a procedure similar to the creation of null mutant strains by transposon mutagenesis.\(^\text{12,13}\) Importantly, the deletion and insertion mutants were also selected and tested under different culture conditions that may impact \(\delta\)-alanine auxotrophy. Moreover, our recent studies on the mechanism of action of \(\delta\)-cycloserine (DCS) in both *M. smegmatis* and *M. tuberculosis* support our prior conclusions that Alr is nonessential and that \(\delta\)-alanine ligase is the lethal target of DCS in both mycobacterial species.

Resolution of the controversy surrounding alr conditional essentiality in mycobacteria is important, not only in the context of the role of Alr but also for its implications in the design of more effective drugs and vaccines targeting the endogenous synthesis of \(\delta\)-alanine in *M. tuberculosis*. Additionally, evidence of horizontal gene transfer in mycobacteria\(^\text{14-18}\) highlights the impact that the potential transfer of genes involved in an alternative pathway of \(\delta\)-alanine biosynthesis in a nonpathogenic species such as *M. smegmatis* might have on TB epidemiology and management. To address this issue, we undertook an NMR metabolomics study to determine whether \(\delta\)-alanine could be exchanged into the metabolic pool of the *M. smegmatis* alr insertion mutant TAM23. We report conclusive evidence of this exchange that suggests an alternative pathway of \(\delta\)-alanine biosynthesis in *M. smegmatis*.

### MATERIALS AND METHODS

#### Bacterial Strains and Culture Conditions

Bacterial strains used in this study were *M. smegmatis* wild-type mc\(^2\)155\(^\text{19}\) and alr mutant TAM23.\(^\text{11}\) For all experiments, strains were grown to an OD\(_{600}\) of 0.6 to 1.0 at 37 °C with shaking at 200 rpm in Middlebrook 7H9 complete media (MADC) supplemented with 0.2% (v/v) glycerol, 0.05% Tween 80, 0.01% cycloheximide, and ADC (0.5% bovine serum albumin (BSA) fraction V, 0.01 M glucose, and 0.015 M NaCl). Cycloheximide is a protein synthesis inhibitor, which was used to suppress the growth of yeast in the bacterial cell cultures. When necessary, cultures were supplemented with 50 mM \(\delta\)-alanine. For growth curve analysis, all cultures were inoculated to a starting OD\(_{600}\) of \(\sim\)0.01, and the generation times were determined as previously described.\(^\text{20}\)

#### Proteomics Sample Preparation and Data Collection

All mc\(^2\)155 and TAM23 cultures (50 mL) were grown to an OD\(_{600}\) of 0.8 to 1.1 in MADC media without \(\delta\)-alanine. The bacteria were removed, stored on ice for 10 min, and centrifuged at 3000 rpm at 4 °C for 15 min. The supernatant was removed from the cell pellet, filtered, and placed at \(-80\) °C. Two washes with 30 mL of ddH\(_2\)O were performed, and the pellet was resuspended for a final volume of 1.0 mL in 50 mM ammonium bicarbonate containing 8 M urea and 1.5 mM phenyl-methyl-sulfonyl fluoride as a protease inhibitor. Cell lysis in the MP Biomedicals FastPrep-24 was performed three times for 20 s with a 5 min chill period between cycles. Two cycles of centrifugation were performed to remove cell debris. Protein (0.5 to 1 mg) was precipitated with cold acetone. Samples were vortexed and incubated overnight at \(-20\) °C. Samples were then warmed to room temperature and pelleted by centrifugation at 14,000 g for 20 min, and the supernatant was discarded. After air-drying for 15–30 min, samples were subjected to MudPIT analysis at the University of Nebraska-Lincoln (UNL) Redox Biology Center Proteomics and Metabolomics Core Facility. A protease and trypsin digest was performed on the protein mixtures and then subjected to liquid chromatography electrospray mass spectrometry LC–ESI–MS. Protein identification was performed by a Mascot database search.\(^\text{21}\)

#### NMR Metabolomics Sample Preparation

General procedures for the handling and preparation of *M. smegmatis* NMR samples for metabolomics analysis have been described elsewhere.\(^\text{22}\) Metabolomics samples for 1D \(^1\)H NMR experiments were prepared from 10 replicates of both *M. smegmatis* mc\(^2\)155 and TAM23 cell cultures. *M. smegmatis* mc\(^2\)155 and TAM23 strains were grown at 37 °C with shaking at 200 rpm in 50 mL of MADC media in a 250 mL flask for 10–12 h until an OD\(_{600}\) of 0.6 to 1.0. A second set of 10 replicate cultures per strain was grown under the same condition with the exception that the TAM23 cultures were supplemented with 50 mM \(\delta\)-alanine after the OD\(_{600}\) reached \(\sim\)0.6. All of the bacterial cultures were then allowed to grow for an additional 2 h. The cell cultures were placed on ice for 5 min and kept on ice throughout the entire process of metabolome extraction. Bacterial cells were harvested by centrifugation at 2000g at 4 °C for 15 min in 50 mL tubes. The cells were washed twice with 30 mL of ice-cold double-distilled water. The cell pellets were resuspended with 1.0 mL of double-distilled water and transferred to a 2 mL vial containing 0.1 mm silica beads (Lysing Matrix B). The cells were then lysed for 40 s at 6 m/s using a MP Biomedicals FastPrep-24. The cell lysate was centrifuged for 10 min at 12,400 g and 4 °C. The supernatant was extracted and then lyophilized and resuspended with 1.0 mL of 100% D\(_2\)O containing 50 mM phosphate buffer (uncorrected pH 7.2) with 50 μM 3-(trimethylsilyl) propionic-2,2,3,3-d\(_4\) acid sodium salt (TMSP). The samples were vortexed and then centrifuged. A 600 μL portion of the cell free extract was then transferred to an NMR tube. A total of 40 metabolomics samples were prepared for collecting 1D \(^1\)H NMR spectra.

NMR metabolomics samples for 2D \(^1\)H–\(^1\)C HSQC experiments were prepared from triplicate *M. smegmatis* mc\(^2\)155 and TAM23 cultures grown in 110 mL of MADC media (250 mL flasks). The bacterial cultures were grown at 37 °C with shaking at 200 rpm for 10–12 h until an OD\(_{600}\) of \(\sim\)0.6. The culture media was then supplemented with or without 100 μM \(^{13}\)C\(_2\)-\(\delta\)-alanine, and the cultures were allowed to grow for an additional 2 h. The bacterial cells were processed and the metabolome was extracted following the same protocol described above.

#### NMR Data Collection

The NMR data were collected and processed according to our previously described protocol.\(^\text{23}\) The NMR spectra were collected on a Bruker Avance DRX 500 MHz spectrometer equipped with a 5 mm triple-resonance cryogenic probe (\(^1\)H, \(^{13}\)C, \(^{15}\)N) with a z-axis gradient, BACS-120 sample changer, and an automatic tuning, and a matching accessory was utilized for automated NMR data collection. 1D \(^1\)H NMR spectra were collected with Purge solvent saturation,\(^\text{24}\) a \(^1\)H 90° pulse of 8 μs, and a spectral width of 5482.5 Hz and 32k data points at 298 K. A total of 16 dummy scans and 128 scans were used.
with a recycle delay of 1.5 s for a total acquisition time of 10 min per spectrum.

A series of three time-zero 2D $^1$H−$^{13}$C HSQC spectra (HSQC0) were collected using the pulse sequence described by Hu et al. for determination of absolute metabolite concentration changes. The NMR spectra were collected with 2048 data points and a spectral width of 5000.0 Hz in the direct $^1$H dimension and 64 data points and a spectral width of 17605.6 Hz in the indirect $^{13}$C dimension. A total of 16 dummy scans and 64 scans with a relaxation delay of 1.5 s were used to obtain each 2D $^1$H−$^{13}$C HSQC0 spectrum with a total acquisition time of 6 h.

**Multivariate Statistical Analysis**

The 1D $^1$H NMR spectra were processed in our MVAPACK software suite (http://bionmr.unl.edu/mvapack.php). For principal component analysis (PCA), the 1D $^1$H NMR spectra were processed with a 1.0 Hz exponential apodization function, followed by Fourier transformation, automatic phasing, and normalization with phase-scatter correction (PSC), and referenced to TMSP-D$_4$ (0.0 ppm). The noise- and solvent-containing regions were manually removed, and the spectrum was binned using an adaptive intelligent binning algorithm and Pareto-scaled. For orthogonal projections to latent structures discriminant analysis (OPLS-DA), the NMR data were processed using MVAPACK as described above. The table of integrals was center-averaged and imported into SIMCA version 13.0 (Umetrics) to produce the S-plots. Supervised classification for each group was determined by cell type, with *M. smegmatis* mc2155 defined as the control (or assigned a value of 0) and *M. smegmatis* TAM23 assigned a value of 1. Ellipses were generated for each group in the PCA scores plot using our PCA/PLS-DA utilities. The ellipses correspond to the 95% confidence limits of a normal distribution for each group.

**Metabolite Identification and Measurement of Absolute Concentration Changes**

2D $^1$H−$^{13}$C HSQC spectra were processed using NMRPipe. The spectra were Fourier-transformed, manually phased, and baseline-corrected. The processed 2D $^1$H−$^{13}$C HSQC spectra were then analyzed using NMRView to assign chemical shifts, intensities, and volumes to each NMR resonance. Chemical shift lists were assigned to specific metabolites using the Human Metabolome Database, Madison Metabolomics Database, and the Platform for Riken Metabolomics. A chemical shift error tolerance of 0.05 and 0.40 ppm was used for $^1$H and $^{13}$C chemical shifts, respectively. The identification of metabolites and metabolomics pathways from the NMR metabolomics data was further verified using the Kyoto Encyclopedia of Genes and Genomes (KEGG) and MetaCyc databases.

Metabolite peak volumes from the HSQC0 experiment were calculated as previously described. In brief, peak volumes from a 2D $^1$H−$^{13}$C HSQC experiment are dependent on the magnitude of J-coupling constants, relaxation processes, dynamics, and metabolite concentrations. The HSQC0 experiment is a series of three HSQC experiments with an increasing number of HSQC pulse sequence repetitions (i.e., HSQC, HSQC$_2$, HSQC$_3$). In this manner, the HSQC peak volume will decrease proportional to the number of pulse sequence repetitions due to the impact of all factors except concentration. A natural log plot of peak volumes versus the increment number (1, 2, 3) allows for the extrapolation back to increment 0 or zero-time, which is proportional to the metabolite’s
concentration. The calibration of metabolite peak volumes from the HSQC0 experiments with an absolute concentration was calculated with a standard calibration curve as previously described. In brief, five different mixtures containing nine different 13C-labeled metabolites (2-keto-3-methylbutyrate, 2-ketobutyrate, acetate, alanine, fructose, glucose, glycine, pyruvate, succinate) with a range of known concentrations (5 to 300 μM) were used to collect a series of HSQC0 experiments. The HSQC0 peak volumes were determined for each metabolite at each concentration, as described above. The HSQC0 peak volumes were then plotted versus the known metabolite concentrations to yield a standard calibration curve. The triplicate HSQC0 experiments were used to calculate averages and standard deviations for each metabolite concentration.

**RESULTS**

**Growth Curves of M. smegmatis alr Mutants**

When grown in MADC, the wild-type and the alr insertion mutant were still able to proliferate in the absence of D-alanine. In our original studies, we observed that TAM23 grew with a significant lag time when subcultured from an inoculum grown in media with D-alanine. However, in this study we subcultured from inocula prepared after the cells were passaged in media without D-alanine. Under these conditions, both strains yielded growth curves that followed similar trends (Figure 1A). Strains mc2155 and TAM23 grew with a generation time of 208 ± 34 and 294 ± 29 min, had an initial lag phase of 5 and 12 h, and reached saturation densities (OD 600 ) of 2.5 and 2.1, respectively. A similar result was obtained for both strains when the media was supplemented with D-alanine except for a moderately higher saturation density for TAM23 (Figure 1B). Strains mc2155 and TAM23 had generation times of 310 ± 28 and 294 ± 33 min, lag phases of 4 and 6.5 h, and saturation densities of 1.7 and 2.54, respectively. When comparing the growth curves with and without D-alanine, TAM23 was able to grow more efficiently in the presence of D-alanine, while the opposite was true for mc2155. Even though the slopes during the exponential phase of growth are significantly different (p value <0.001) when comparing TAM23 grown in no D-alanine to mc2155 grown with and without D-alanine and TAM23 with D-alanine, there does not appear to be a biological difference. These results demonstrate that the alr gene is not essential for the survivability of M. smegmatis in the absence of D-alanine and that an alternative pathway for synthesizing D-alanine must exist.

**Major Proteomic Changes in M. smegmatis alr Mutants**

MudPIT analysis identified 904 proteins expressed in media without D-alanine. TAM23 protein overexpression was defined as a 10-fold or greater expression level relative to mc2155. Thirty-one proteins were identified as being overexpressed in TAM23 relative to mc2155 (Supplemental Table S1). Several mc155 and TAM23 grew with a generation time of 208 ± 34 and 294 ± 29 min, had an initial lag phase of 5 and 12 h, and reached saturation densities (OD 600 ) of 2.5 and 2.1, respectively. A similar result was obtained for both strains when the media was supplemented with D-alanine except for a moderately higher saturation density for TAM23 (Figure 1B). Strains mc2155 and TAM23 had generation times of 310 ± 28 and 294 ± 33 min, lag phases of 4 and 6.5 h, and saturation densities of 1.7 and 2.54, respectively. When comparing the growth curves with and without D-alanine, TAM23 was able to grow more efficiently in the presence of D-alanine, while the opposite was true for mc2155. Even though the slopes during the exponential phase of growth are significantly different (p value <0.001) when comparing TAM23 grown in no D-alanine to mc2155 grown with and without D-alanine and TAM23 with D-alanine, there does not appear to be a biological difference. These results demonstrate that the alr gene is not essential for the survivability of M. smegmatis in the absence of D-alanine and that an alternative pathway for synthesizing D-alanine must exist.

**Major Proteomic Changes in M. smegmatis alr Mutants**

MudPIT analysis identified 904 proteins expressed in media without D-alanine. TAM23 protein overexpression was defined as a 10-fold or greater expression level relative to mc2155. Thirty-one proteins were identified as being overexpressed in TAM23 relative to mc2155 (Supplemental Table S1). Several
enzymes directly involved in central carbon metabolism were affected by the \textit{alr} mutation. Specifically, alanine dehydrogenase (ALD) and several alcohol dehydrogenases (ADHs) were all overexpressed in TAM23. The ADH enzymes exhibited an approximate 40-fold increase in TAM23 relative to mc\textsuperscript{155}. Similarly, ALD was upregulated by \textsim -30-fold in TAM23.

**Metabolic Impact of Media Lacking \textit{D-Alanine} on \textit{M. smegmatis alr} Mutants**

The set of 1D \textsuperscript{1}H NMR spectra were used to assess the global metabolome differences between wild-type \textit{M. smegmatis} mc\textsuperscript{155} and the alanine racemase TAM23 insertion mutant (Figure S1). The PCA scores plot (Figure 2A) compares the metabolomes of \textit{M. smegmatis} mc\textsuperscript{155} cells and the TAM23 insertion mutant grown in MADC without \textit{D-alanine}. The scores plot reduces the complex 1D \textsuperscript{1}H NMR spectrum that captures the state of the cellular metabolome into a single point in principal component space (PC1, PC2, etc.). Correspondingly, the principal components represent the largest variations between the individual 1D \textsuperscript{1}H NMR spectra. The scores plot indicates that PC1 and PC2 account for 51.0 and 21.0\% of the variation in the NMR spectra, respectively. A total of 10 replicates for the wild-type mc\textsuperscript{155} and the \textit{alr} TAM23 insertion mutant form two distinct clusters in the PCA scores plot. The unsupervised PCA model demonstrates a statistically significant difference between the metabolomes of \textit{M. smegmatis} wild-type mc\textsuperscript{155} cells and the \textit{alr} TAM23 insertion mutant.

An OPLS-DA model was generated from the metabolomics data sets to further characterize the mc\textsuperscript{155} and TAM23 metabolome and to identify the discriminatory variations that maximize group separation.\textsuperscript{39} The OPLS-DA model without the addition of \textit{D-alanine} yielded a reliable fit, as evident by an R\textsuperscript{2} of 0.652, R\textsuperscript{2} of 0.971, and a Q\textsuperscript{2} of 0.923 (Figure S2A). Importantly, cross-validation using CV-ANOVA produced a statistically significant \textit{p} value of 5.17 \times 10\textsuperscript{-6}, indicating a valid OPLS-DA model. The group separation between the alanine racemase TAM23 mutant and the mc\textsuperscript{155} wild-type metabolomes is statistically significant, which is consistent with the group separation observed in the PCA scores plot. Furthermore, an S-plot generated from the OPLS-DA model identified the NMR spectral differences and, correspondingly, the major metabolome changes contributing to the group separations in the scores plot (Figure 2B). The variables (chemical shifts) with a large modeled correlation [approximately 1 (correlated) or \textsim -1 (anticorrelated)] and large modeled covariation \geq 0.1 or \leq -0.1 were identified as key contributors to group separations in the OPLS scores plot and are labeled on the S-plot. The metabolites from the S-plot identified as major contributors to group separation in the absence of supplemental \textit{D-alanine} are summarized in Table 1.

**Impact of \textit{D-Alanine} on the Metabolome of \textit{M. smegmatis alr} Mutants**

The NMR metabolomics experiment was repeated using \textit{M. smegmatis} mc\textsuperscript{155} and TAM23 cells grown in MADC supplemented with 50 mM \textit{D-alanine}. As previously observed, the PCA scores plot contained two distinct clusters, indicating a difference between the mc\textsuperscript{155} and TAM23 metabolomes (Figure 2C). PC1 and PC2 account for 68.5 and 13.7\% of the variation in the data, respectively.

The OPLS-DA model without the addition of \textit{D-alanine} yielded a reliable fit as evident by R\textsuperscript{2} of 0.682, R\textsuperscript{2} of 0.981, and a Q\textsuperscript{2} of 0.957. Importantly, cross-validation using CV-ANOVA produced a statistically significant \textit{p} value of 4.39 \times 10\textsuperscript{-10}, indicating a valid OPLS-DA model. The group separation between the alanine racemase TAM23 mutant and the mc\textsuperscript{155} wild-type metabolomes is statistically significant, which is consistent with the group separation observed in the PCA scores plot. The S-plot from OPLS-DA model was used to identify the chemical shifts (metabolites) that significantly contributed to the group separation in the OPLS-DA scores plot (Figure 2D). The metabolites from the S-plot identified as major contributors to group separation in the presence of supplemental \textit{D-alanine} are summarized in Table 1.

**Quantitative Analysis of Metabolite Changes in \textit{M. smegmatis alr} Mutants**

The NMR metabolomics experiment was repeated using \textit{M. smegmatis} mc\textsuperscript{155} and TAM23 cells grown in MADC supplemented with 100 \textmu M of \textsuperscript{13}C-labeled [\textsuperscript{13}C\textsubscript{2}]-\textit{D-alanine}. Triplicate sets of \textsuperscript{13}C-labeled metabolite extracts were prepared per strain and then analyzed using time-zero \textsuperscript{1}H-\textsuperscript{13}C HSQC (HSQC\textsubscript{0}) experiments.\textsuperscript{25,26} A 2D \textsuperscript{1}H-\textsuperscript{13}C HSQC NMR spectrum allows for easier identification of metabolites because of the reduced complexity and spectral overlap compared with a 1D \textsuperscript{1}H NMR spectrum. Only metabolites that originate from the supplemental \textsuperscript{13}C-D-alanine are observed in the 2D \textsuperscript{1}H-\textsuperscript{13}C HSQC spectrum (Figure S3). Each peak in the 2D \textsuperscript{1}H-\textsuperscript{13}C represents a \textsuperscript{13}C-\textsuperscript{1}H pair for a specific metabolite that were assigned by matching the chemical shifts against NMR metabolomics databases.\textsuperscript{35-38} A total of 38 metabolites were identified from the two \textit{M. smegmatis} strains.

A concentration for each metabolite was determined by extrapolating peak volumes from a series of three 2D \textsuperscript{1}H-\textsuperscript{13}C HSQC spectra at different time points to interpolate a time-zero peak volume. The spectra were collected in triplicate to determine an average peak volume and calculate a standard deviation. The average time-zero peak volume is directly proportional to a concentration based on a calibration curve.

**Table 1. Relative Differences in Metabolite Concentrations between \textit{M. smegmatis} Wild-Type and TAM23 \textit{alr} Mutant Cells**

\caption{Observed increase or decrease in metabolite concentrations in \textit{M. smegmatis} TAM23 \textit{alr} mutant cells relative to wild-type mc\textsuperscript{155} cells. Metabolites were identified from the S-plots generated from the corresponding OPLS-DA model (see Figure 2). Metabolites in italics exhibited a reversal in concentration depending on whether media were supplemented with or without \textit{D-alanine}.}
\end{table}
using 9^{13}C-labeled compounds of known concentration. A plot of the absolute metabolite concentrations for the M. smegmatis mc^215S and TAM23 strains is shown in Figure 3.

![Figure 3](image-url) Figure 3. Bar graph summarizing metabolite concentrations determined from 2D ^1H−^13C HSQC_0 experiments. M. smegmatis mc^215S (blue) and TAM23 (red) cell cultures were supplemented with 100 μM ^13C-labeled [13C]−d-alanine. Statistical significance at the 95% confidence level is denoted by a black asterisk, and a red asterisk indicates a statistical significance after applying Bonferroni multiple hypothesis correction. (insert) Expanded view of an overlay of the wild-type strain mc^215S (blue) and alr insertion mutant TAM23 (red) 2D ^1H−^13C HSQC_0 spectra highlighting alanine concentration changes. The full spectral overlay is in the Supporting Information (see Figure S3).

Peptidoglycan precursors such as glutamate, lysine, and N-acetyl-glucosamine were significantly decreased in the alr insertion mutant. The concentration of trehalose, an essential precursor for trehalose-containing glycolipids, which allows the attachment of glycolipids to arabinogalactan in the cell wall was also decreased in the alr insertion mutant.

**DISCUSSION**

Multiple resistant strains of TB are growing and spreading at a rapid pace, and the concurrent loss of antibiotic efficacy is predicted to cause upward of 10 million deaths annually by 2050. Avoiding this potential pandemic requires developing new antibiotics that circumvent common mechanisms of resistance, which necessitates the identification of novel therapeutic targets. For antibiotics, therapeutic targets have commonly been an essential enzyme or protein. Alr is a pyridoxal S′-phosphate (PLP)-containing enzyme that is thought to be necessary for the growth of mycobacteria. The racemization of L-alanine to D-alanine by Alr is the only enzymatic reaction in M. tuberculosis or M. smegmatis to produce the D form of alanine, which is an essential intermediate for peptidoglycan biosynthesis. Nevertheless, the essentiality of Alr in M. smegmatis and M. tuberculosis survivability and its significance as a therapeutic target have been highly controversial.

Chacon et al. previously observed that an alr knockout mutant (TAM23) was able to grow under conditions without supplementing d-alanine into Middlebrook 7H9 or minimal medium. The TAM23 strain did not exhibit any growth defects, but it was clear that the phenotypic changes between TAM23 and the wild-type strain were pronounced. Again, we did not observe any biologically significant differences when we compared the TAM23 growth curve, upon passage for growth in media without d-alanine, to the wild-type mc^215S strain in the absence of d-alanine (Figure 1A). In fact, we observed a higher saturation density for the TAM23 growth curve relative to mc^215S with the addition of d-alanine to the culture media (Figure 1B). One potential interpretation is that the stress response TAM23 experiences due to the lack of both alr activity and d-alanine is partly relieved by supplemented d-alanine, leading to a relative improvement in cell growth. Regardless, TAM23 does not exhibit any growth defects in the absence or presence of d-alanine, strongly implying that the alr inactivation does not negatively impact cell survivability. This is in direct conflict with other studies that show Alr to be essential in mycobacteria. These discrepancies may be attributed to contrasting mutant construction and cell growth conditions. TAM23 is an insertion mutant, which still has the potential of producing a protein product with residual or defective activity. However, as discussed above, this possibility is extremely unlikely as the insertion mutation would be similar to a transposon insertion in the middle of the gene. Furthermore, we previously examined Alr activity in TAM23 and did not detect any activity above BSA background (Figure 1C). The lack of Alr activity in TAM23 was also supported by examining the steady-state concentrations of L- and d-alanine. L-Alanine was observed to accumulate in TAM23, which is consistent with an inactive Alr (Figure 1D). Conversely, the d-alanine production in TAM23 was below that of mc^215S but still above background levels. This is consistent with the alr mutant producing d-alanine through an alternative mechanism. Recently, we proposed an alternative metabolic pathway for the production of d-alanine in M. tuberculosis and M. smegmatis to compensate for an inactive Alr.

An alternative source of d-alanine may result from an unidentified transaminase converting pyruvate into d-alanine. This hypothesis resulted from a metabolomics investigation into the in vivo lethal target of DCS, in which Alr and D-alanine-D-alanine ligase (Ddl) had been previously identified as likely targets for DCS. We identified Ddl as the in vivo lethal target of DCS based on an observed decrease in the biosynthesis of d-alanyl-d-alanine that occurred simultaneously with a DCS-induced inhibition on cell growth. We also previously observed that the incorporation of ^13C-carbons from d-alanine into glutamate was dependent on DCS concentration, which strongly suggests a transaminase compensating for an inactive Alr.

Herein, we further tested our hypothesis that Alr is nonessential for peptidoglycan biosynthesis and the survivability of M. smegmatis by examining the total proteomic and metabolic shifts that occur in TAM23 relative to wild-type mc^21S cells. Our proteomics analysis revealed that ALD and ADH enzymes were significantly overexpressed from Alr inactivation. Of particular note, ALD is involved in a metabolic recycling process, which includes an alternative pathway for the
biosynthesis of d-alanine. ALD catalyzes the oxidative deamination of L-alanine to produce pyruvate and ammonia with concomitant formation of NADH. Thus ALD may provide an alternative source of d-alanine via pyruvate, where pyruvate and D-glutamate are then converted into D-alanine and α-ketoglutarate by a transamination reaction. A D-amino acid aminotransferase (Dat) capable of catalyzing this transamination reaction has been previously observed in Bacillus subtilis, Listeria monocytogenes, and numerous other bacteria. While not verified, we previously identified a number of enzymes that may potentially perform the same function in M. smegmatis. In the absence of supplemental d-alanine, the overproduction of ALD in TAM23 increases the reducing potential (generation of NADH). This is compensated for by the overproduction of ADH enzymes to generate NAD through the oxidation of NADH. Thus this metabolic change is necessary to maintain redox balance when Alr is inactive.

The increase in ammonia production from an elevated ALD activity did not lead to an observable toxicity for M. smegmatis. In fact, ammonia is a preferred source of nitrogen for M. smegmatis and is a usable substance that participates in many metabolic processes. In eukaryotes, the increase in ammonia production from an elevated ALD activity did not lead to an observable toxicity for M. smegmatis. In fact, ammonia is a preferred source of nitrogen for M. smegmatis and is a usable substance that participates in many metabolic processes. In eukaryotes, the increase in ammonia production from an elevated ALD activity did not lead to an observable toxicity for M. smegmatis. In fact, ammonia is a preferred source of nitrogen for M. smegmatis and is a usable substance that participates in many metabolic processes.

From a 1D 1H NMR metabolomics study we observed statistically significant differences between the mc2155 and TAM23 metabolomes based on the distinct clusters in the PCA scores plot (Figure 2A). The metabolite changes identified from the resulting S-plot (Figure 2B) are listed in Table 1. As previously observed, the differences in the mc2155 and TAM23 metabolomes was eliminated when TAM23 was complemented with the wild-type alr gene. Conversely, supplementing the growth media with D-alanine had no effect; the mc2155 and TAM23 global metabolomes are still significantly different (Figures 2C,D and Table 1). The pronounced differences between the mc2155 and TAM23 metabolomes persist because a clear switch in the metabolic state of TAM23 ensues when TAM23 is cultured in the presence or absence of D-alanine. TAM23 cells enter an anabolic state when D-alanine is not readily available. Intriguingly, when D-alanine is available to TAM23, we observe a complete reversal in the flow of carbon through some metabolic processes. In effect, the addition of D-alanine circumvents the need for a metabolic response to replace the missing D-alanine due to the Alr inactivation. Instead, TAM23 simply directs the D-alanine into peptidoglycan biosynthesis, which then allows the cell to pursue normal metabolic processes. Nevertheless, TAM23 still exhibits a distinct metabolism compared with mc2155. For instance, fatty acids are increased in TAM23 relative to mc2155, presumably to redirect fatty acids to increase cell-wall integrity. The metabolites that exhibited a reversal in cellular concentrations based on the availability of D-alanine are colored in the metabolic pathways in Figure 4. Indeed, supplementation with D-alanine induced a metabolic switch for TAM23, as revealed by the 1D 1H NMR metabolomics experiments (Figure 4B).

Figure 4. (A) Metabolic network map displays the 2D 1H−13C-HSQC time zero absolute metabolite concentration differences between M. smegmatis wild-type mc2155 and alr insertion mutant TAM23 grown in MADC media and treated at midexponential phase with [13C2]-D-alanine. A positive blue bar indicates a concentration increase in mc2155 relative to TAM23. A negative red bar indicates a concentration decrease in mc2155 relative to TAM23. The plotted concentrations are on a micromolar scale and the error bars represent standard deviations. Metabolites highlighted in magenta exhibited a reversal in concentration depending on whether media were supplemented with or without D-alanine from the 1D 1H NMR experiments and Table 1. L-Alanine dehydrogenase (ALD), highlighted in red, was overexpressed in TAM23 relative to mc2155. The dark arrows identify the primary carbon flux pathway, blue arrows represent a hypothetical pathway for D-alanine biosynthesis that is depicted in detail in panel B, and the dotted lines represent established alternative routes. (B) Metabolic network summarizing the 1D 1H NMR data and the D-alanine acid pools (see Figure 1D and Table 1) comparing mc2155 with TAM23 from cultures without supplemental D-alanine. Metabolites colored blue were observed to increase in mc2155 relative to TAM23. Diagram adapted from ref 51.
To further evaluate the metabolic response due to alr inactivation, we traced the distribution of $^{13}$C-carbon derived from $[^{13}$C$_2]$D-alanine throughout the TAM23 and mc$^{155}$ metabolome using 2D $^1$H-$^{13}$C HSQC NMR experiments (Figures 3 and 4A). In M. tuberculosis and M. smegmatis, D-alanine can be directly converted into L-alanine (by Alr), into D-alanyl-D-alanine (by Ddl), into pyruvate (by an unidentified transaminase), or into alanine-poly(glycerolphosphate)/D-alanine-poly(phosphoribitol). As expected, alr inactivation causes more of the supplemented D-alanine to be biosynthesized into D-alanyl-D-alanine in TAM23 relative to mc$^{155}$. More notably, a drastic decline is observed in the conversion of D-alanine into glutamate and pyruvate along with an accumulation of $[^{13}$C$_2]$D-alanine in TAM23. This is consistent with an inactive Alr in TAM23 that prevents the D-alanine carbon from entering into other metabolic pathways besides peptidoglycan biosynthesis.

In fact, a likely pathway is the conversion of D-alanine into pyruvate by the unidentified transaminase, which, apparently, is significantly less efficient than Alr in directing the supplemental D-alanine into central carbon metabolism. Conversely, the supplied D-alanine is not essential to peptidoglycan biosynthesis in mc$^{155}$ because Alr is still active. Instead, D-alanine can be used as an alternative carbon source by converting it into L-alanine, which is then diverted into other metabolic processes. We observed an increase in the conversion of $[^{13}$C$_2]$D-alanine into glucose, fructose-6-phosphate, pyruvate, glutamate, GABA, succinate aspartate, and citrulline for mc$^{155}$ (Figures 3 and 4A). This indicates an increase in the flow of carbon through glycolysis, the TCA cycle, and urea cycle, with a simultaneous decrease from peptidoglycan biosynthesis. Notably, the 1D $^1$H NMR experiments indicate an increase in the cellular concentration of citrulline, glutamate, and succinate for TAM23 with supplemental D-alanine. This apparent discrepancy highlights the fact that the different NMR experiments actually measure two distinctly different metabolic changes. The 1D $^1$H NMR experiments measure the total pool of these metabolites within the cell culture regardless of the carbon source. Conversely, the 2D $^1$H-$^{13}$C HSQC experiment is only measuring the amount of citrulline, glutamate, and succinate derived from the supplied $[^{13}$C$_2]$D-alanine. The observed changes in the concentrations of GABA and glutamate for TAM23 may also be indicative of a stress response resulting from an inactive Alr in our mutant strain especially in conditions without D-alanine.$^{36}$ The decrease in GABA and glutamate derived from $[^{13}$C$_2]$D-alanine are consistent with D-alanine being shunted into other critically needed metabolites, where other carbon sources may be used for GABA and glutamate production.

**CONCLUSIONS**

Taken together, these new data uniformly agree with the hypothesis of an inactive Alr in TAM23 and an alternative transaminase as a source of D-alanine for TAM23 (Figure 4). Our results further confirm that Alr is not an essential enzyme in M. smegmatis. Because central metabolic pathways are conserved in mycobacteria, these results also suggest that Alr is not essential in M. tuberculosis and that Alr inhibitors will not have a bactericidal action.
